What is a Differential Equation?

A function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ is a relationship between numbers. For example, if $f(x, y) = x^2 - y^2$, the equation $f(x, y) = k$ has solutions which are pairs of numbers (x_0, y_0) satisfying $x_0^2 - y_0^2 = k$.

Relationships between numbers are great, but we're graduating to relationships between functions. Consider

$$\frac{d}{dx} : \{\text{functions}\} \rightarrow \{\text{functions}\}.$$

We might then consider $D(f) = \frac{df}{dx}$ and ask for the set of solutions to

$$D(f) = 0.$$

From calculus you know that the only functions with zero derivative everywhere are constant functions. Thus, $D(f) = 0$ has solutions $f(x) = k$ for constant k .

What about $D(f) = f$? This equation has solutions $f(x) = 0$ and $f(x) = ke^x$ for any constant k .

Equation where the solutions are functions are called *functional equations*.

Differential Equation

DEF

A functional equation that involves derivatives is called a **differential equation**. An differential equation is called **ordinary** if it is a differential equation without partial derivatives.

We sometimes abbreviate *ordinary differential equation* as ODE.

In this class, we'll only deal with ordinary differential equations.

Why is this idea useful? Derivatives capture rates of change, and rates of change seem to relate to all sorts of quantities in nature. So, in a word, *modeling*.

Examples of Differential Equations

1. From physics, if you're in a uniform gravitational field, the change in your velocity is constant with respect to time. That is,

$$\frac{dv}{dt} = a.$$

You've discovered acceleration!

2. Newton's law of cooling states that if $T(t)$ is the temperature of a body at time T and W is the ambient temperature, then

$$\frac{dT}{dt} = \alpha(T - W)$$

for some α .

3. Imagine you're hungry. Let $A(t)$ be your appetite at time t , and let $F(t)$ be how much food you've eaten. You might imagine

$$F'(t) = \alpha A(t). \quad (\text{What would this mean?})$$

Now, if T is the capacity of your tummy, you might also imagine

$$A'(t) = \frac{-\beta}{T - F(t)}. \quad (\text{Is this reasonable?})$$

This is a *system* of differential equations.

You might also suspect that it takes time for your appetite to change after you've eaten food. We could model this with the equation

$$A'(t) = \frac{-\beta}{T - F(t - k)}$$

for some time delay k .

You can dream up differential equations to model just about any situation. However, there is a cruel fact of life: *almost all differential equations do not have elementary closed-form solutions*. That is, almost every differential equation you dream up, you won't be able to write down a formula for its solution.

Because of this, we will largely focus on modeling and estimating behavior of solutions and what we can do with solutions, rather than how to solve particular differential equations.

Terminology

A differential equation (or system) is called n th order if $\frac{d^n}{dx^n}$ is the highest order derivative that appears.

A differential equation is called *linear* if it can be written in the form

$$h_n(t) \frac{d^n f(t)}{dt^n} + h_{n-1}(t) \frac{d^{n-1} f(t)}{dt^{n-1}} + \cdots + h_1(t) \frac{df(t)}{dt} + h_0(t) f(t) + h(t) = 0$$

for some function h_n, \dots, h_1, h_0, h that depend only on t . (It will turn out that linear differential equations with constant coefficients is one of the few types of differential equations we know how to solve.) If $h(t) = 0$ for some linear differential equation, it is called *homogeneous*.

Visualizing first order ODE's

Suppose we rewrite a first order ODE as

$$f'(t) = F(t, f(t)).$$

We can visualize this differential equation with a *slope field*. Letting $y = f(t)$, we can plot in the ty -plane little line segments representing the slope at each point.

Let's visualize $f'(t) = f(t) + t$.

Looking at the slope field, we could imagine curves whose slope follows the pattern of the field a curve that *flows* along the slope field).

If we specify *initial conditions*, like $f(-1) = 0$, we've specified that $(-1, 0)$ lies on our solution curve in the t - y -plane. From the picture, it looks like $f(t) = -t - 1$ is the corresponding solution, and checking, indeed this is a solution for the given initial conditions!

Specifying different initial conditions, like $f(0) = 0$, we expect to see a totally different solution curve. The solution for these initial conditions is $f(t) = e^{t-1} - t - 1$.

We can see from the slope field that depending on the initial condition, there are several different “looks” a solution may have. The line $y = -t - 1$ seems to divide the set of initial conditions into solutions that curve up and those that curve down.

Can we see this from the equation?

Consider the two cases, one where our initial conditions start above $f(t) = -t - 1$ and the other where they start below.

$f < -t - 1$. In this case, $f + t < 1$. From the differential equation $f' = f + t$, we can see that the slope starts out negative. In particular $f' = \alpha < -1$. If we increase t by a small amount, f will decrease by approximately $\alpha \Delta t$. Thus, our new slope will be $f'_{\text{new}} \approx f + t + \alpha \Delta t + \Delta t = f + t + (1 + \alpha) \Delta t < -1$ since $1 + \alpha < 0$. Not only that, $f'_{\text{new}} < f'$. So, given these initial conditions, we'd expect the solution to head towards negative y values at a faster and faster rate.

$f > -t - 1$. In this case, we get the opposite of what we got before. As t increases, $f' = f + t$ increases, and so we expect solutions whose slope increases as t increases. Further, after at most 1 unit of increase in t , we expect $f' > 0$.

In the example $f' = f + t$, there was a solution for every initial condition. Recall that a solution is a *function* that satisfies the differential equation and the initial conditions. Sometimes we can see patterns in the slope field that are not functions.

For each of the following, draw the slope field and estimate what regions of initial conditions correspond to functions, and how many different “looks” can solutions have.

1. $y' = x/y$
2. $y' = y/x$
3. $y' = e^x$
4. $y' = y(2 - y)$
5. $y' = 3x^2 - 4$
6. $y' = x\sqrt{y}$
7. $y' = y^2 - x$
8. $y' = x^2 - y^2$

Euler's Method

Euler's method is the name of a numerical algorithm to approximate the solution to initial value problems. The logic follows from the idea of a linear approximation. If we have $y = f(x)$ and we know y' , we can approximate $f(x + \Delta x) \approx y + \Delta x y' = y_1$. Now, if we have an equation that relates y' to x and y , we can use y_1 to approximate y'_1 , the slope of f at $x + \Delta x$. Once we have that data, we repeat. If our initial step size was small enough, we would expect to get a reasonable numerical approximation.

Euler's Method

Let $y'(x) = f(x, y)$ be a first order ordinary differential equation. The **Euler approximation** to the initial value problem $y' = f(x, y)$ and $(x, y(x)) = (x_0, y_0)$ with step size Δx is the sequence of points (x_i, y_i) given by (x_0, y_0) if $i = 0$ and

$$x_i = x_{i-1} + \Delta x$$

$$y_i = y_{i-1} + f(x_{i-1}, y_{i-1}).$$

The inductive algorithm to generate (x_i, y_i) is called **Euler's Method**.

Euler's method is rather straightforward, but how do we know it actually approximates solutions to the differential equation?

Convergent Approximation

Let $\{(x_i, y_i)_{\Delta x}\}$ be the output of some algorithm $\mathcal{A}(\Delta x)$ for the initial value problem $y' = f(x, y)$ with initial conditions $(x, y) = (x_0, y_0)$. We say $\mathcal{A}(\Delta x)$ **converges** to the solution to the initial value problem if

$$\max_{(x_i, y_i)_{\Delta x}} |y_i - y(x_i)| \rightarrow 0 \quad \text{as} \quad \Delta x \rightarrow 0$$

where y the true solution to the initial value problem.

Euler's method is an algorithm with a tunable parameter, Δx , the step size. Saying that Euler's method converges just amounts to saying that the error in the estimated solution goes to zero as the step size goes to zero.

It'd be swell if Euler's method converged. And, in fact, it does, but not necessarily all the time.

Consider the initial value problem $y' = f(x, y)$ with initial conditions (x_0, y_0) . Further suppose $\|\nabla f(x, y)\| \leq M$ for $(x, y) \in [x_0, x_0 + T] \times \mathbb{R}$. Then Euler's method converges on the interval $[x_0, x_0 + T]$.

Proof. Let y^* be the true solution to the initial value problem. We must show that the Euler approximates (x_i, y_i) have bounded total distance from $(x_i, y^*(x_i))$.

To do this, we will consider two types of error. Let d_i be the *local error* for (x_i, y_i) and let e_i be the *total error* at (x_i, y_i) . That is, let y_i^* be the solution to the initial value problem $y' = f(x, y)$ with initial conditions (x_i, y_i) . Then,

$$d_i = \underbrace{y_{i-1}^*(x_{i-1} + \Delta x)}_{\text{how much we should have changed by}} - \underbrace{(y_{i-1} + f(x_{i-1}, y_{i-1})\Delta x)}_{\text{next step}},$$

and

$$e_i = \underbrace{y_i}_{\text{approximation}} - \underbrace{y^*(x_i)}_{\text{exact value}}.$$

If we can show $|e_i| \rightarrow 0$, we'd be done! We will do this by bounding the local errors, d_i , and then showing that if they are small enough, e_i will also be small.

To bound d_i , let's use our knowledge of linear approximations. Since y_{i-1}^* is a solution to an initial value problem, it is differentiable. Further, since ∇f exists, y_{i-1}^* is actually twice differentiable. In any case,

$$\begin{aligned} y_{i-1}^*(x_{i-1} + \Delta x) &= y_{i-1} + y_{i-1}^*{}' \Delta x + \eta_i(\Delta x) \\ &= y_{i-1} + f(x_{i-1}, y_{i-1})\Delta x + \eta_i(\Delta x) \end{aligned}$$

where $\eta_i(\Delta x)/\Delta x \rightarrow 0$ as $\Delta x \rightarrow 0$. Thus,

$$d_i = \eta_i(\Delta x).$$

Now, we'll bound the total error at the i th step.

$$e_i = y^*(x_i) - y_i$$

$$= \underbrace{y^*(x_{i-1}) + f(x_{i-1}, y^*(x_{i-1}))\Delta x + \eta_{i-1}^*(\Delta x)}_{\text{exact expansion of } y^*} - \underbrace{(y_{i-1} + f(x_{i-1}, y_{i-1})\Delta x)}_{y_i},$$

where $\eta_{i-1}^*(\Delta x)$ is again an error term that goes to zero as $\Delta x \rightarrow 0$.

Collecting terms, we now see

$$\begin{aligned} e_i &= y^*(x_{i-1}) - y_{i-1} + \left(f(x_{i-1}, y^*(x_{i-1})) - f(x_{i-1}, y_{i-1}) \right) \Delta x + \eta_{i-1}^*(\Delta x) \\ &= e_{i-1} + \left(f(x_{i-1}, y^*(x_{i-1})) - f(x_{i-1}, y_{i-1}) \right) \Delta x + \eta_{i-1}^*(\Delta x). \end{aligned}$$

However, we supposed $\|\nabla f\| \leq M$, so

$$\left| f(x_{i-1}, y^*(x_{i-1})) - f(x_{i-1}, y_{i-1}) \right| \leq M |y^*(x_{i-1}) - y_{i-1}| = M |e_{i-1}|.$$

Putting this all together, we see

$$|e_i| \leq |e_{i-1}| + M |e_{i-1}| \Delta x + |\eta_{i-1}^*(\Delta x)| = (1 + M \Delta x) |e_{i-1}| + |\eta_{i-1}^*(\Delta x)|.$$

Let $d = \max\{|\eta_1|, |\eta_2|, \dots, |\eta_1^*|, |\eta_2^*|, \dots\}$. We now have the recursive formula

$$\begin{aligned} |e_i| &\leq (1 + M \Delta x) |e_{i-1}| + d \\ &\leq (1 + M \Delta x) ((1 + M \Delta x) |e_{i-2}| + d) + d = (1 + M \Delta x)^2 |e_{i-2}| + (1 + (1 + M \Delta x)) d \\ &\leq (1 + M \Delta x)^i |e_0| + \sum_{k=0}^{i-1} (1 + M \Delta x)^k d. \end{aligned}$$

Since $e_0 = 0$ by construction, we know

$$|e_i| \leq \sum_{k=0}^{i-1} (1 + M \Delta x)^k d = \frac{(1 + M \Delta x)^i - 1}{M \Delta x} d.$$

Now since $1 + t \leq e^t$, we may replace $1 + M \Delta x$ by $e^{M \Delta x}$ to finally get

$$|e_i| \leq \frac{e^{iM \Delta x} - 1}{M} \cdot \frac{d}{\Delta x}.$$

Since we are approximating in the interval $[x_0, x_0 + T]$, we know $i \Delta x \leq T$, and so

$$|e_i| \leq \frac{e^{MT} - 1}{M} \cdot \frac{d}{\Delta x},$$

and so e_i is bounded by a constant times $d/\Delta x$. Since d was the maximum of errors from first order approximations whose derivatives were uniformly bounded, we know $d/\Delta x \rightarrow 0$ as $\Delta x \rightarrow 0$. However, we assumed something even stronger. We assumed that ∇f existed and so $y^{*''}$ and $y_i^{*''}$ exist. Thus, we actually have $d/(\Delta x^2) \rightarrow k$, which means the error in our approximation decreases *linearly* with the size of Δx . \square

Linear ODE's with Constant Coefficients

All solutions to the differential equation $y' - ky = 0$ are of the form Ae^{kt} . And since e^{kt} “stays the same form” when differentiated, it’s a good candidate for guessing solutions to differential equations.

Consider the second-order differential equation

$$y'' - 4y = 0.$$

If we guess $f(t) = e^{kt}$ as a solution we see,

$$k^2 e^{kt} - 4e^{kt} = (k^2 - 4)e^{kt} = 0.$$

We know $e^{kt} \neq 0$, this equation can only hold true if $k^2 - 4 = 0$ and so $k = \pm 2$ provides solutions: $f(t) = e^{2t}$ and $f(t) = e^{-2t}$. However, these aren’t all the solutions. We can multiply either of these solutions by a constant and we get additional solutions of the form Ae^{2t} and Be^{-2t} .

Have we found all of the solutions? We can try to answer this question by seeing if we can solve a random initial value problem. Let's use the initial conditions

$$y(0) = 1 \quad \text{and} \quad y'(0) = 1.$$

(Since this is a second order ODE, we can specify both y and y' for initial conditions.)

Testing $y(t) = Ae^{2t}$, we see that if $A = 1$ then $y(0) = 1$. But then $y'(0) = 2$, which isn't what we want. Testing $y(t) = Be^{-2t}$, again we see if $B = 1$, $y(0) = 1$, but now $y'(0) = -2$, which isn't what we want either! Is this initial value problem unsolvable, or are there other solutions lurking?

What if we tried something random like $f(t) = e^{2t} + e^{-2t}$. Then, $f'' - 4f = 0$. Son of a gun! We've found a missing solution.

We can check that $f(t) = Ae^{2t} + Be^{-2t}$ is a solution to the differential equation as well, for any choice of A and B .

Now testing, $f(0) = A + B = 1$ and $f'(0) = 2A - 2B = 1$ has solutions of $A = 3/4$ and $B = 1/4$. Whew, the initial value problem had a solution after all!

What's really going on here?

Linear

DEF

A function T is called **linear** if $T(\alpha a + \beta b) = \alpha T(a) + \beta T(b)$ for scalars α, β . Here, a and b need to be objects that can be added and scaled.

The definition of linear is very general. We only need that a, b are objects that can be added and scaled and that α, β are scalars.

Are we already familiar with some linear functions? You betcha! Let $\vec{n} \in \mathbb{R}^3$ and consider $T : \mathbb{R}^3 \rightarrow \mathbb{R}$ defined by $T(\vec{v}) = \vec{n} \cdot \vec{v}$. We now have

$$T(\alpha \vec{v} + \beta \vec{w}) = \vec{n} \cdot (\alpha \vec{v} + \beta \vec{w}) = \alpha \vec{n} \cdot \vec{v} + \beta \vec{n} \cdot \vec{w} = \alpha T(\vec{v}) + \beta T(\vec{w}).$$

So, T is linear! This function T looks very familiar—eerily like normal form of a plane. Normal form of a plane is

$$\vec{n} \cdot \vec{x} = k,$$

and normal form of a plane through the origin is

$$\vec{n} \cdot \vec{x} = 0.$$

Here, both equations look like “linear function(\vec{x}) = constant.”

Now consider the function $D : \{\text{functions}\} \rightarrow \{\text{functions}\}$ defined by

$$D(f) = \frac{df}{dx}.$$

Is D linear? Well, functions can definitely be scaled and added to each other, so they qualify as objects that could be fed into a linear function. Also, if f, g are functions and $\alpha, \beta \in \mathbb{R}$, then

$$D(\alpha f + \beta g) = \frac{d(\alpha f)}{dx} + \frac{d(\beta g)}{dx} = \alpha \frac{df}{dx} + \beta \frac{dg}{dx} = \alpha D(f) + \beta D(g).$$

So D is linear!

Consider the differential equation $y'' - 2y' - y = 0$. If we let

$$F(h) = \frac{d^2h}{dx^2} - 2\frac{dh}{dx} - h,$$

we can again check that F is linear, and our differential equation can be rephrased as $F(y) = 0$. Again, a linear function equals a constant.

Now suppose that y and y^* are both solutions to $F(h) = 0$. By linearity we see

$$F(Ay + By^*) = AF(y) + BF(y^*) = 0 + 0 = 0,$$

so $Ay + By^*$ is again a solution to the differential equation. So, just like the sum of any two direction vectors for a plane was a direction vector, so is the linear combination of any two solutions to a homogeneous linear differential equation.

What about a non-homogeneous linear ODE? Consider $y'' - 2y' - y = t$. This is equivalently represented as $F(y) = t$. This looks similar to a plane that doesn't pass through the origin.

Just by guessing a polynomial solution, we can compute $F(at + b) = 2a - (at + b) = t$ when $a = -1$ and $b = 2$. Therefore $y(t) = -t + 2$ is a solution. If f were a solution to the homogeneous ODE $F(f) = 0$, then $y + Af$ would be a solution to the original ODE by linearity. Computing,

$$F(y + Af) = F(y) + AF(f) = t + A0 = t.$$

The set of all solutions to $F(y) = t$ now takes a form very similar to vector form of a plane. Namely, $y + Af + Bg + \dots$ where y is a particular solution and f, g, \dots are solutions to the corresponding homogeneous system.

Can we prove that every solution to $F(y) = t$ is of the form a particular solution + a solution corresponding solution to the homogeneous system?
